Acknowledgements

Throughout the work on this thesis I have received a great deal of help and support from several people. I am deeply indebted to my faculty advisor, Dr. James Hitchcock, for the invaluable guidance and assistance he provided throughout my research. Without his help, this thesis might not have been completed. In any experimental research, problems with the equipment will inevitably arise. I would like to thank all of the technicians in the Aeronautics/Astronautics laboratories at AFIT, especially Leroy Cannon, for their help on the numerous occasions when problems with my equipment came up. Finally, I wish to thank my fiance Mike for his continual support and encouragement during my entire thesis work.

Abstract

Research was performed to verify previously obtained friction coefficients for compressible, laminar and turbulent flow in a simulated heat pipe for intermediate mass injection and suction rates. The research was divided into two main parts: an experimental study and a numerical study.

In the experimental study, a simulated heat pipe consisting of a long porous tube with air injected into one end to simulate the evaporator and extracted from the other end to simulate the condenser was investigated. Axial static pressure variations for various air supply mass flow rates were measured. It was found that the friction in the pipe decreased the amount of pressure recovery at the end of the pipe and that this decrease became even greater with increased supply mass flow rate.

The pressure distributions obtained in the experimental study were used as input for a numerical simulation in the numerical portion of this research. A steady, one-dimensional computer code was developed to simulate the porous pipe system used in the experimental study in order to calculate Mach numbers, axial Reynolds numbers, and friction coefficients along the pipe. Newton's second law, continuity, and Shapiro's method of influence coefficients were used in the computer simulation to calculate the flow properties. The results

obtained for the friction coefficients in the porous pipe system studied did not correlate with the values predicted by Bowman's expressions. They did, however, exhibit the general trend expected for the friction coefficient - axial Reynolds number product with Mach number.

COMPRESSIBLE FRICTION COEFFICIENTS IN A SIMULATED HEAT PIPE

I. Introduction

The purpose of this introductory chapter is to acquaint the reader with the history and operation of the heat pipe and the goals of this research. The chapter is divided into three sections. The first section provides a brief discussion of the development and operation of the heat pipe, while in the second section the pertinent literature is reviewed. In the last section, the objectives of this study are outlined.

Development and Operation of the Heat Pipe

The concept of the heat pipe was first conceived by R.S. Gaugler in 1942 (4:1). The first serious development work took place many years later by G.M. Grover and his associates at the Los Alamos Scientific Research Laboratory in 1964 (4:1). Grover showed that the heat pipe is an effective high-performance heat transmitter, developed some applications for it, and gave it its present name. Following Grover's work, interest in the heat pipe quickly grew for both terrestrial and space applications, resulting in numerous papers and several books being written on the subject. Today heat pipes have numerous applications. Some of these applications include cooling nuclear reactors, infrared sensors, laser systems, generators,

electronic and electrical equipment, and turbine blades. Heat pipes have also been used for cryogenic eye surgery, in spacecraft for temperature control of spacesuits and vehicles, and for heat collection from solar energy, geothermal energy, and exhaust gases.

The operation of the heat pipe is similar to that of the thermal syphon, shown in Figure 1.1. The thermal syphon consists of a sealed tube, from which the air has been evacuated, with a small quantity of liquid placed inside. When the end of the tube is heated, it causes the water to vaporize and move to the cooler end of the tube where it condenses on the walls. The condensate then returns to the other end of the tube by means of gravity. The thermal syphon is limited in its orientation since the evaporator region must be at the lowest end. The heat pipe, however, consists of a closed tube with a porous capillary wick fixed to the inside surface, in its conventional form (Figure 1.2). The wick contains the liquid phase of the working fluid while the remaining volume of the tube, known as the vapor region, contains the vapor phase of the working fluid. When heat is applied to evaporator end, the fluid in that section of the pipe is vaporized. This creates a pressure difference down the pipe and causes the vapor to flow from the evaporator end to the condenser end where the vapor condenses and releases its latent heat of vaporization to a heat sink. The evaporation process depletes the liquid in the evaporator section and causes the liquid-vapor interface to move into the wick

Figure 1.1 Diagram of the Thermal Syphon

Figure 1.2 Components and Operation of a Conventional Heat Pipe (3:2)

surface, see Figure 1.3. A capillary pressure then develops which pumps the condensate back to the evaporator section. The quantity of heat capable of being transported as latent heat of vaporization is normally several orders of magnitude greater than the quantity that can be transported as sensible heat in a conventional convective system (3:1,2). This efficiency allows the heat pipe to transport large amounts of heat with a small size and a very small temperature difference between the two ends.

Figure 1.3 Development of Capillary Pressure at the Liquid-Vapor Interface (3:2)

Background Literature

As was stated in the previous section, numerous papers have been written on heat pipe theory and operation. This study is concerned primarily with the effect of mass injection and extraction on the friction coefficient at the tube wall.

Several articles have been written on this subject, but only a few of these will be discussed in this section.

Kinney (5) studied the effect of wall mass transfer on the frictional and heat transfer characteristics of fully developed laminar flow in circular porous tubes. His results are based on the assumptions of a constant-property fluid and uniform wall mass transfer and are presented for radial Reynolds numbers (Reynolds numbers based on the velocity of the flow through the tube wall and the tube diameter) ranging from -4.618 to 20. Using numerical solutions to the tube flow and energy equations, he found that the friction coefficient, f , was a function of both the radial and axial Reynolds numbers, Re_w and Re_x , respectively. For large values of Re_w , the values of the product $f \cdot Re$ asymptotically approached the value 19.739. He also found that the wall friction decreased with increased extraction radial Reynolds number and that for a given axial Reynolds number fluid injection caused an increase in the wall friction.

Yuan and Finkelstein (11) studied the effects of uniform wall injection and extraction on two-dimensional laminar incompressible flow in a tube with porous walls. They used a perturbation method to solve the Navier-Stokes equations in cylindrical coordinates, and they observed that fluid injection at the wall accelerated the main stream velocity and thus increased the velocity gradient at the wall. The wall frictional coefficient was therefore found to increase with injection and decrease with suction.

Kinney and Sparrow (6) used an analytical model to investigate the effects of surface suction on friction, heat transfer, and mass transfer for turbulent flow inside a tube. They found that the shear force was greater when suction was present than when it was absent and that high Reynolds number flows are more sensitive to suction than low Reynolds number flows. They also observed that in the presence of suction the momentum change of the flow tended to increase the pressure in the flow direction, while the wall shear stress tended to decrease the pressure.

For his doctoral dissertation at the Air Force Institute of Technology in 1986, Bowman numerically and experimentally investigated the effects of mass injection and extraction on the wall frictional coefficients (2). Bowman developed functional relationships for friction coefficients to be used in one-dimensional heat pipe vapor models to design heat pipes for compressible-flow situations with large mass injection and extraction rates. Bowman used a simulated heat pipe with air as the working fluid and found that the friction coefficient in general is a function of Re_w , Re_m , Mach number and the ratio of pipe length to diameter. For laminar flow, he found the relationship to be

$$f \cdot Re_m = 16(1.2337 - 0.2337 \exp(0.0363 Re_w)) \times \exp(6 Ma^2/5) \quad (1.1)$$

and for turbulent flow

$$f = f^* [1 + 55 \text{Re}^{0.2} (v/u)^{0.2} (2L_e/D)^{0.2} \exp(6\text{Ma}^2/5)] \quad (1.2)$$

where

$$f^* = 0.046/\text{Re}^{1/4} \quad (1.3)$$

where v is the radial velocity, u is the average axial velocity, D is the pipe inside diameter, and L_e is the length of the condenser.

Objective and Scope

The main objective of this research is to verify Bowman's friction coefficient expressions for intermediate radial Reynolds number compressible flow. To accomplish this, a simulated heat pipe and a numerical simulation were used. The axial pressure variation was experimentally measured along the simulated heat pipe. This pressure distribution was used as input to a numerical model designed to model one-dimensional compressible and incompressible flow in a tube with mass injection and extraction. The numerical model utilized the pressure distribution to solve for the friction coefficient distribution along the pipe. For axial flow Mach numbers less than 0.01, Newton's second law and incompressible flow equations were used to solve for the flow properties; while for Mach numbers greater than 0.01, compressible flow, the continuity equation and Shapiro's method of influence coefficients (9) were employed. The numerical results were then compared to the values predicted by Bowman's expressions.

II. Experimental Model

The purpose of the experimental portion of this study was to obtain data on the pressure distribution for flow inside a simulated heat pipe at intermediate radial Reynolds numbers. This was accomplished by means of a simulated heat pipe modeled after the one used by Bowman (2) in his research. The sample pressure distributions were then used as input to a numerical model, to be discussed in Chapter III, in order to calculate the friction coefficient distribution. This chapter discusses how the heat pipe vapor flow was simulated and the experimental configuration used to model the flow.

Heat Pipe Simulation

A simulated heat pipe was used because of its advantages over an actual heat pipe in experimental studies. The design consisted of two porous pipes of equal length placed end to end with air injected through the walls of one pipe to model the evaporator and extracted through the walls of the other pipe to model the condenser. Wageman and Guevara (10) and Quale and Levy (8) showed that this system simulates the vapor dynamics in a heat pipe quite well. One advantage of the simulated heat pipe is that it is much simpler to build and test. Heat pipes typically operate at low pressures with very small axial pressure gradients, making it difficult to measure pressures. The porous pipe system eliminates this problem since it operates at higher pressures with larger pressure gradients,

yet still accurately simulates flow in an actual heat pipe. In addition, this system does not require complicated heating and cooling equipment nor does it require a liquid return mechanism (similar to a wick in a heat pipe).

Experimental Apparatus

As was mentioned earlier, the experimental set up used in this investigation was modeled after that used by Bowman. Much of the same equipment he used was used for this experiment as well; for this reason, only a brief description of the set up will be given. The reader is referred to Bowman's dissertation for additional details.

In order to obtain intermediate radial Reynolds numbers a longer porous pipe with a smaller diameter than that used by Bowman was required. A polyethylene porous pipe produced by Porex Technologies with a nominal pore size of 35 microns, a 5/8 inch inside diameter and 3/4 inch outside diameter was the smallest diameter pipe found. Since this pipe was only slightly smaller in diameter than Bowman's, the length of the test section was increased to approximately seven feet. The pipe selected was only available in four foot lengths; therefore, two four foot pipes were chosen. One three inch section was cut from both ends of each pipe for calibration tests leaving two 3-1/2 foot pipes. One pipe was used to model the evaporator and was enclosed in a manifold designed and built to supply the air for injection. The injected air was passed through a filter just prior to entering the test configura-

tion. The other pipe, used to model the condenser, was left open to the atmosphere. A diagram of the set up is shown in Figure 2.1. The two pipes were placed end to end so that the air injected into the first porous pipe would flow into the second pipe where it would be extracted through the walls of the pipe into the atmosphere.

In the original test configuration, twelve pressure taps were installed, six evenly spaced in each pipe. When pressure measurements were made, it was found that the pressure varied along the tube more than expected in the condenser section; so 15 additional pressure taps were added to that section. The final configuration is shown in Figure 2.1. Twenty-seven pressure taps were used in the porous pipes, six in the evaporator section spaced six inches apart and twenty-one in the condenser section spaced every two inches. In addition, five other pressure taps were used in the system. Two were used to measure the pressure around the orifice plate, one above the plate and one below the plate. One tap was used to measure the pressure at the upstream end of the air supply manifold and two taps were used to measure the pressure at the downstream end of the manifold. Stainless steel 0.060 inch outside diameter tubes were used as pressure taps. The tubes were inserted and cemented into 0.058 inch diameter holes in the porous pipe to produce a tight fit. The stainless steel tubes were installed such that their ends were flush with the inside wall of the porous pipe.

Figure 2.1 Experimental Test Configuration

Pipe Calibration

The calibration of the porous pipe was made using a relationship developed by M. Muskat (7:66). Muskat found that the mass flux through a porous medium is related to the pressure difference across the porous medium by the following expression:

$$(\Delta p^2) = A(pv)^2 + B(pv) \quad (2.1)$$

Each of the four porous pipe samples taken from the pipe used in the test configuration were installed into the test manifold designed by Bowman (Figure 2.2). For each sample, Δp^2 and pv were measured at various mass flow rates. The

Figure 2.2 Porous Pipe Calibration Manifold
(Bowman 2:29)

curve was expected to be very close to linear at very low mass flow rates, with the contribution of the $A(pv)^2$ term being quite small compared to the $B(pv)$ term. This linear behavior was observed in that region, however the curve was offset from the origin by the amount $\Delta p^2 = 126,921.84 \text{ lbf}^2/\text{ft}^4$. These results are shown in Figure 2.3. This offset in the curve was probably due to the tendency of the pressure transducer in the Scanivalve to read the pressures higher than what they actually were. The atmospheric pressure readings made by the Scanivalve were consistently higher than those taken from the barometer in the laboratory. To correct for this effect, the offset value was subtracted from each Δp^2 reading. The values for the constants A and B in Equation (2.1) were calculated using a least squares technique to curve fit the corrected calibration data and were found to be $4.679 \times 10^8 \text{ ft}^2/\text{sec}^2$ and $4.2843 \times 10^7 \text{ lbf}/\text{ft-sec}$, respectively. The final calibration results are shown in Figures 2.4 and 2.5. Figure 2.5 is an enlargement of the region of the graph in Figure 2.4 for the low mass flow rates. Equation (2.1) was needed for the numerical model to determine the mass flux for a given pressure differential across the pipe walls.

Data Measurement and Acquisition

A Zenith Z-100 computer was used for the data acquisition. Pressure measurements were made using a T-type Scanivalve, from Scanivalve Corporation, with a model PDCR42 differential pressure transducer having a pressure range of -100 to 100

Figure 2.3 Porous Pipe Calibration Data Showing Offset From Origin

Figure 2.4 Porous Pipe Calibration Results

Figure 2.5 Enlargement of $\Delta(p^2)$ Range 0 - 500,000 lb-f²/ft⁴ in Calibration Results

psig. A Dual Systems Control model AIM12 analog-to-digital card in the computer was used to digitize the pressure transducer input into the computer. The offset option on the card and amplification were set to read signals from -100 to +100 mV with a resolution of 0.048 mV. Fifty data samples were averaged for each point to reduce noise. For mass fluxes above 0.035 lbf-sec/ft², a square-edged orifice plate was used to measure the total mass flow rate entering the test configuration. The pressure differential across the orifice plate was measured using both the Scanivalve and a water manometer. The mass flow rate was calculated using the following expression (1):

$$\dot{m} = 0.52502(CYd^2F_o)(\rho_1(p_1 - p_2)^{1/2}/(1 - \beta_o)) \quad (2.2)$$

where

$$C = K/E = K(1 - \beta_o)^{1/2} \quad (2.3)$$

$$K = K_o(1 + A/Re_d) \quad (2.4)$$

$$K_o = K_L[10^4 d / (10^4 d + 15A)] \quad (2.5)$$

$$\begin{aligned} K_L = & .5993 + .007/D + (.364 + .076/D^{1/2})\beta_o \\ & + .4(1.63 - 1/D)[(.07 + .5/D) - \beta_o]^{3/2} \\ & - (.009 + .034/D)(.5 - \beta_o)^{3/2} \\ & + (65/D^2 + 3)(\beta_o - .7)^{3/2} \end{aligned} \quad (2.6)$$

$$A = d(830 - 5000\beta + 9000\beta^2 - 4200\beta^3 + 530/D^{1/2}) \quad (2.7)$$

$$Y = 1 - (.41 + .35\beta_o^4)(X/k) \quad (2.8)$$

$$X = P/P_1 \quad (2.9)$$

$$Re_d = 40m/\pi\mu d \quad (2.10)$$

Very low mass flow rates, such as those measured in the calibration tests, were measured using a flowmeter with a range of 0 to 0.44 cfm. The pressure was measured at a point just upstream of the flowmeter in order to calculate the density of the air. In addition, a valve was installed just downstream of the flowmeter to vary the upstream pressure in order to read higher mass flow rates with the meter. It was important to get accurate readings in the low mass flow rate region because there were several sections of the simulated heat pipe where the injection/suction rates were quite small. Equation (2.1) with the constants A and B calculated from data for mass fluxes only above 0.04 lbf-sec/ft² underpredicted the mass fluxes at low Δp^2 .

Experimental Results

The pressure variation obtained along the pipe was a result of two effects: the friction encountered along the pipe walls and the rate of change in momentum along the pipe. The total effect of the friction force was manifested in the pressure drop between the two ends, or the lack of complete pressure recovery. The pressure drop due to friction was found to increase with increased mass flow rate. Figure 2.6 shows the pressure distribution for five different mass flow rates. Additional data for other mass flow rates can be found in Appendix A. As mass was added in the evaporator region, $0 < X/L < 0.5$, the fluid accelerated with increasing X/L with a corresponding drop in pressure. The mass removal

in the condenser section caused the flow to decelerate and the pressure to rise.

Figure 2.6 Axial Pressure Distributions

III. Numerical Model

This chapter describes the numerical model used to simulate the flow generated by the experimental model. The governing equations used to solve for the flow properties will be discussed first, followed by a description of the solution technique used. Finally, the results obtained will be presented.

Governing Equations

All of the flowfields generated with the experimental configuration contained sizable regions of very low Mach number ($Ma < 0.1$). Therefore, two models were used in the numerical simulation: an incompressible model for Mach numbers less than 0.01, and a compressible model for Mach numbers greater than 0.01. One-dimensional, steady, adiabatic flow was assumed for both models.

Incompressible Model. The incompressible model consisted primarily of Newton's second law and incompressible flow relations. To approximate the shear stress at the pipe wall, Newton's second law was applied to an element of fluid in the pipe (Figure 3.1).

Figure 3.1 Element of Fluid for Equation of Motion

Applying Newton's second law for steady flow to the fluid element gives

$$\dot{m}_2 u_2 / g_c - \dot{m}_1 u_1 / g_c = (p_1 A_1 - p_2 A_2) - \tau_w A_w \quad (3.1)$$

where A_w is the wall surface area for the increment Δx .

Equation (3.2) can be solved for τ_w giving

$$\tau_w = [\dot{m}_1 u_1 / g_c - \dot{m}_2 u_2 / g_c + (p_1 - p_2) A_c] / A_w \quad (3.2)$$

where A_c is the cross-sectional area equal to A_1 and A_2 . The expression for the friction coefficient is given by

$$f = 2 \tau_w g_c / \rho \bar{u}^2 \quad (3.3)$$

where

$$\bar{u} = (u_1 + u_2) / 2 \quad (3.4)$$

Substituting the expression for τ_w given by Equation (3.2) in Equation (3.3) gives an expression for the friction coefficient in terms of quantities which can be calculated from the input pressure distribution

$$f = 2 [\Delta H + (p_1 - p_2) A_c] g_c / \rho \bar{u}^2 A_w \quad (3.5)$$

where

$$\Delta H = \dot{m}_1 u_1 / g_c - \dot{m}_2 u_2 / g_c \quad (3.6)$$

The axial velocities along the pipe were calculated from a mass balance on an element of fluid in the pipe (Figure 3.2).

Figure 3.2 Element of Fluid Used For Mass Balance

Performing the mass balance on the fluid element in Figure 3.2

$$\rho_2 u_2 A_m = \rho_1 u_1 A_m - (pv)_{avg} A_p \quad (3.7)$$

where $(pv)_{avg}$ is the average mass flux through the pipe walls over the increment Δx found by applying Equation (2.1) at stations 1 and 2 (shown in Figure 3.2) and taking the average of the two. The negative sign on the quantity $(pv)_{avg}$ is a result of the sign convention on the mass flux. For injection, (pv) is considered negative and considered positive for suction. Equation 3.7 can be solved for u_2 giving

$$u_2 = \rho_1 u_1 / \rho_2 - (pv)_{avg} A_p / \rho_2 A_m \quad (3.8)$$

The velocity u_1 is taken from the previous step and its initial value is zero.

The pressure at each step was found by interpolating from the input pressure distribution using a second degree interpolation formula. Figure 3.3 illustrates this interpolation procedure.

Figure 3.3 Pressure Interpolation

Referring to Figure 3.3 for $x_1 < x < x_3$, $p(x)$ is given by

$$p(x) = p_1 K_1 + p_2 K_2 + p_3 K_3 \quad (3.9)$$

where

$$\begin{aligned} K_1 &= [(x - x_2)(x - x_3)] / [(x_1 - x_2)(x_1 - x_3)] \\ K_2 &= [(x - x_1)(x - x_3)] / [(x_2 - x_1)(x_2 - x_3)] \\ K_3 &= [(x - x_1)(x - x_2)] / [(x_3 - x_1)(x_3 - x_2)] \end{aligned} \quad (3.10)$$

The temperature (T), viscosity (μ), axial Reynolds number (Re_m), and radial Reynolds number (Re_w) were calculated from the following expressions:

$$T = T_o / [1 + (k - 1) Ma^2 / 2] \quad (3.11)$$

$$\mu = 2.27E-08 (T)^{3/2} / (T + 198.6) \quad (3.12)$$

$$Re_m = 4 \dot{m}_{avg} / (\pi D \mu g_o) \quad (3.13)$$

$$Re_w = (\rho v)_{avg} D / (\mu g_o) \quad (3.14)$$

where T in Equation (3.11) is in degrees Fahrenheit, and \dot{m}_{avg}

is the average of m_1 and m_2 . Equations (3.5), (3.8) - (3.14), and (2.1) thus comprise the equations for the incompressible model.

Compressible Model. The compressible model consisted of Equations (3.9) - (3.14) along with the differential form of the continuity equation and Shapiro's method of influence coefficients for Mach number variation with friction and wall mass transfer to solve for the velocity and friction coefficient, respectively. The differential form of the continuity equation in terms of pressure, temperature and Mach number is given by

$$\frac{dm}{m} = \frac{dp}{\rho} + \frac{dMa}{Ma} + \frac{1}{2} \frac{dT}{T} \quad (3.15)$$

Using the equation of state for an ideal gas, $\rho = p/RT$, and Equation (3.11) in equation 3.15 gives the differential form of the continuity equation in terms of pressure and Mach number.

$$\frac{dm}{m} = \frac{dp}{p} + \frac{1}{2} \left[\frac{1 + (k - 1)Ma^2}{1 + (k - 1)Ma^2/2} \right] \frac{d(Ma)^2}{Ma^2} \quad (3.16)$$

Equation (3.16) can then be integrated to solve for Ma_2 , which is given by the following expression

$$Ma_2^2 = \{-1 + [1 + 2(k - 1)C]\}/(k - 1) \quad (3.17)$$

where

$$C = Ma_1^2 (1 + (k - 1)Ma_1^2/2) (\dot{m}_2/\dot{m}_1)^2 / (p_2/p_1)^2 \quad (3.18)$$

The equation for Mach number variation with friction and wall mass transfer utilizing Shapiro's method of influence coefficients is given by

$$d(Ma^2)/Ma^2 = F_s 4f dx/D + F_w \frac{dm}{m} \quad (3.19)$$

where F_s and F_w are the influence coefficients defined by

$$F_s = Ma^2(1 + (k - 1)Ma^2/2)/(1 - Ma^2) \quad (3.20)$$

$$F_w = 2(1 + kMa^2)[1 + (k - 1)Ma^2/2]/(1 - Ma^2) \quad (3.21)$$

where x is the axial coordinate. Equation (3.19) can be rearranged into the following form

$$\frac{(1 - Ma^2) dMa^2}{kMa^2[1 + (k - 1)Ma^2/2]} = \frac{4f dx}{D} + \frac{2(1 + kMa^2)}{kMa^2} \frac{dm}{m} \quad (3.22)$$

Equation (3.22) is in a form which can be integrated to yield an expression for the friction coefficient. After performing the integration and rearranging, the following expression results

$$f = D[\ln(Ma_1^2/Ma_2^2) - C_m \ln(p_2/p_1)] / (2\Delta x) \quad (3.23)$$

where

$$C_m = (1 + k\overline{Ma^2})/(k\overline{Ma^2}) \quad (3.24)$$

$$\overline{Ma^2} = (Ma_1^2 + Ma_2^2)/2 \quad (3.25)$$

and where Ma_2^2 is found from Equation (3.17) and Ma_1^2 is taken from the previous step. Equations (3.9) - (3.15), (3.17), (3.23) and (2.1) form the set of equations used in the compressible model.

Solution Method

A marching technique was used to solve for flow properties along the simulated heat pipe. The pressure information obtained from the experimental work was first read in to the program; then the various constants for the pipe geometry and the air properties and the variables at the upstream end of the pipe were set. The set of equations for the incompressible model were then solved to find the Mach number, axial Reynolds number, and friction coefficient for each Δx increment along the pipe until a Mach number of 0.01 was reached. After that, the compressible model equations were used to determine the properties. Sample calculations for the first iteration made by the program are given in Appendix B and a copy of the code used is included as Appendix C.

To verify the accuracy of the numerical simulation, three checks were made in the program. The first check was a comparison of the mass flow rate entering the condenser with the mass flow rate entering the air supply manifold for the evaporator to see if the two were equal. The second check was a force balance over the entire pipe. When considering the pipe as a whole, the only forces acting on the fluid are the pressures at the two ends and the total wall shear force (see Figure 3.4).

Figure 3.4 Force Balance on Entire Heat Pipe

A summation of these forces gives

$$\Sigma F = (p_u - p_e)A_m - \tau_w A_p \quad (3.26)$$

where A_p is the surface area of an increment Δx of pipe. Ideally, this summation should be zero, since the drop in pressure between the two ends of the pipe is a result of the wall shear stress. The last check made was a mass balance over the entire pipe to see if the total mass injected into the pipe equaled the total mass removed from the pipe.

Numerical Results

All of the numerical simulations made using the code in Appendix C modeled the porous pipe system used in the experimental study for various supply mass flow rates. The results are plotted as the friction coefficient - axial Reynolds number product ($f \cdot Re$) versus Mach number for the evaporator in Figure 3.5 and for the condenser in Figure 3.6.

Figure 3.5 Effect of Compressibility in Evaporator

Figure 3.6 Effect of Compressibility in Condenser

IV. Discussion of Results

This chapter discusses the results obtained in both the experimental and numerical portions of this research. The reader is referred to Figure 2.6 for the discussion of the experimental results and to Figures 3.5 and 3.6 for the discussion of the numerical results.

Experimental Results Discussion

An important part of the experimental study was the calibration of the porous pipe. It was particularly important to obtain accurate data for the very low mass flux range, $0.0 - 0.005 \text{ lbf-sec/ft}^2$, since the simulated heat pipe operated with several regions of very low mass flux. The four pipe samples taken from the porous pipe used in the test configuration were originally calibrated using the orifice plate-water manometer system (described in Chapter II) to measure the mass flow rate entering the test sample. This system only allowed measurements of mass flow above approximately $0.03 \text{ lbf-sec/ft}^2$, since the ratio of the orifice plate bore to the air supply pipe diameter was 0.327 and values of the discharge coefficient are not available for ratios below 0.3. Curve-fitting the data from these first calibration tests produced values for the constants A and B in Equation (2.1) which under-predicted the mass flux for small values of Δp^2 . Further calibration tests were then made on two of the four samples, one sample from the pipe used in the evaporator section and one

from the pipe used in the condenser section, using a flowmeter with a range of 0 - 0.44 cfm. Only two of the samples were calibrated because the other two were too dirty and clogged from the first set of calibration tests to yield accurate results. The data obtained from the second set of calibration tests exhibited the linear behavior expected in the low mass flux region, but the curve showed an offset from the origin, where it should have passed through. This offset probably resulted from a combination of two things. One is that the pressure transducer tended to give pressure readings that were too high. This was observed when the transducer readings for the atmospheric pressure were compared to the readings taken from the barometer in the laboratory, which is considered the more accurate of the two. The transducer consistently gave higher readings than the barometer, by approximately 1%. The other possible reason for the offset in the curve is the fact that the atmospheric pressure used to calculate the Δp^2 values was taken from the barometer, not from the pressure transducer. Therefore in each of the Δp^2 terms, the pressure value for the inside of the pipe was too high and the external pressure value was fairly accurate thus making the Δp^2 values higher than they actually were. As was stated in Chapter II, the offset was corrected for by subtracting the amount of the offset from each of the Δp^2 readings. The constants obtained using the additional calibration data yielded values for the constants A and B that improved the results in the low mass flux region. Upon examining the range of mass fluxes in the

simulated heat pipe, it was found that most of the mass flux values were below $0.05 \text{ lbf-sec/ft}^2$. Another curve-fit was then made of only the calibration data up to $0.05 \text{ lbf-sec/ft}^2$, which produced values for A and B that further improved the results in the low mass flux region. Since the walls of the pipe used in these experiments were approximately half as thick as those used in Bowman's experiments, the value of B was expected to be less than the value that Bowman calculated. As it turned out, this value was about one fourth that of Bowman's.

The pressure distributions obtained from the tests with the simulated heat pipe showed a fluctuation in the pressure distribution in the condenser section rather than a smooth increase of pressure from the beginning to the end of the condenser. Kinney and Sparrow (6) noted that in the presence of wall suction, the change in momentum of the flow tended to increase the pressure in the flow direction, while the wall shear stress tended to decrease the pressure. In the first half of the condenser, the change in momentum was very small due to the small amount of suction through the walls and was approximately the same order of magnitude as the wall shear stress. Therefore the momentum change was not the dominant effect in this region and consequently the pressure did not exhibit a smooth increase.

Due to the compressible nature of the flow and the low design pressure drop across the pipe walls, the mass injection and removal along the pipe studied was non-uniform. As

was discussed previously, the mass flux through the pipe wall is dependent on the pressure difference across the pipe wall. Since the external pressure was relatively constant and the internal pressure varied axially along the pipe, the mass injection and removal also varied. The thinness of the pipe walls made the pressure drop across the pipe low, thus presenting less resistance to the mass flux. The pipe's internal pressure consequently remained quite close to the external pressure for a large portion of both the condenser and the evaporator sections. The pressure dropped off sharply in the last six inches of the evaporator, where most of the mass addition occurred, and rose sharply in the last half of the condenser, where most of the mass was removed. This suggests that there may be an optimum length or L/D for the pipe.

Numerical Results Discussion

In all of the numerical simulations, the flow in the evaporator section was assumed to be laminar throughout. This was a reasonable assumption since Bowman showed that the flow remains laminar, when injection is present, up to very large axial Reynolds numbers (on the order of 10^6). The values of the friction coefficients obtained from the numerical simulations were somewhat higher than the values predicted by Bowman's expression. In the evaporator section, where mass injection was present, Kinney's (5) results indicate that for laminar, incompressible flow with large injection wall Reynolds numbers, the product $f \cdot Re_w$ should approach approximately 20.

For the incompressible region of the evaporator used in this study, the calculated friction coefficients are approximately one order of magnitude greater than Kinney's results. Bowman's laminar flow friction coefficient expression included the effect of the compressibility of the flow and thus extended Kinney's results for higher Mach numbers. Again the calculated friction coefficients are approximately one order of magnitude greater than the values predicted by Bowman's expression. Kinney's and Bowman's results indicate that the product $f \cdot Re$ remains essentially constant (approximately 20) for low Mach numbers and Bowman's expressions predict an increase as the Mach number increases toward 1 and greater. The results from this research were found to exhibit this trend for the $f \cdot Re$ product versus Mach number, which can be seen in Figure 3.5, only the increase with Mach number begins at lower Mach numbers than Bowman's results.

The flow in the condenser section was assumed to be turbulent throughout in all of the numerical simulations. Bowman showed that once the flow entered the condenser, where an adverse pressure gradient was present, it transitioned to turbulent. He also found that the transition always started at the beginning of the condenser near the pipe wall, when the flow was subsonic, and then spread toward the center of the pipe as the flow progressed through the condenser. The location in the condenser where the turbulence reached the pipe center moved downstream as the axial velocity increased. Since the transition regions for the axial velocities attained

at the entrance to the condenser in this research were quite small relative to the overall condenser length, neglecting the transition region and assuming turbulent flow throughout was a reasonable assumption. The values computed for the friction coefficients in the condenser section were lower, by approximately one order of magnitude, than the values predicted by Bowman's turbulent flow friction coefficient expression. Bowman's expression indicated an increase in the $f \cdot Re_m$ product with increased Mach number. When the results from the numerical simulation of the condenser were plotted as $f \cdot Re_m$ versus Ma , the trend predicted by Bowman's expression was not seen as prominently as the trend shown in the evaporator, but it was present (see Figure 3.6).

There were several sources of error in the experimental study which could account for the difference between the calculated and expected results. As was mentioned earlier, there was a problem with the pressure transducer in the Scanivalve tending to read the pressures higher than what they actually were. This problem primarily affected the calibration results by giving a higher pressure differential for a given mass flux, which thus introduced error into the computed values of the constants A and B in Equation (2.1). Also there were no pressure taps in the last six inches of the evaporator section, preceding the condenser, where the pressure showed a sharper drop. Therefore, the accuracy of the interpolated pressures in that region is questionable. In all the numerical simulations, the friction coefficients near the end

of the evaporator were negative indicating that the change in momentum across the increment was greater than the change in pressure. This meant that the calibration equation (Equation (2.1)) was giving mass flux values that were too high for the given pressure difference, thus indicating that the calibration constants, A and B, were inaccurate.

The checks made in the numerical simulation code to verify the accuracy of the calculations all indicated that the simulations were giving accurate results. The force balance check yielded quite small positive values in all of the simulations and the mass balance check yielded small negative values for the low supply mass flow rates and small positive values for the higher supply mass flow rates. In all of the simulations, the mass flow rate entering the condenser was found to be too high. To correct this, the equation used to calculate the mass flux through the wall (Equation (2.1)) was multiplied by a correction factor. This correction factor increased with higher supply mass flow rates and ranged from approximately 0.70 to 0.85. The addition of the correction factor also improved the force and mass balances.

V. Conclusions and Recommendations

This chapter discusses the conclusions made from the findings of this research. In addition, a brief list of recommendations for further research is presented.

Conclusions

The data obtained from this research exhibited the same basic trends predicted by previous research, however differing by approximately one order of magnitude. The change in momentum of the flow has much more influence on the pressure change along the pipe than the friction force. Therefore, even though the values of the friction coefficients calculated in this work were much greater than those predicted by Bowman's expressions, the actual difference in the pressure distributions resulting from Bowman's friction values and those measured in the experimental portion of this research may not be as significant. Another numerical simulation utilizing Bowman's friction coefficient expressions to solve for the axial pressure distribution would be needed in order to make the comparison. The friction coefficient calculations were also found to be quite sensitive to the values computed for the calibration constants, A and B. The difference in the friction coefficients calculated from this research and that of Bowman's dropped from two orders of magnitude to one order of magnitude between the second and final curve-fits of the calibration data. The analysis of the results from the nu-

merical simulations seems to indicate that the either the data obtained in the calibration tests is inaccurate or the equation used to curve-fit the data (Equation (2.1)) does not give an accurate enough representation of the calibration results. Whichever is the case, the inaccuracy of the calibration equation seems to be the primary source of the discrepancy with the results from previous research.

Recommendations

Upon examining the procedures used in this study, several recommendations can be made for improvements to this experiment and possibilities for future research. One recommendation which would improve the readings obtained from the pressure transducer is to subtract the transducer's atmospheric pressure reading from each reading made by the transducer to get a gauge pressure. The atmospheric pressure taken from a barometer can then be added to these gauge pressures to get the absolute pressure. This would help eliminate the offset in the calibration curve, which was observed in this study. Some of the recommendations for future research include:

- 1) Perform experiments to measure the velocity gradients along the wall as well as the pressure distribution along the pipe. This would provide more accurate information for computing the shear stress at the wall and should give more accurate results for the friction coefficients.

- 2) Perform a one-dimensional numerical simulation which utilizes Bowman's friction coefficient expressions to solve

for the pressure distribution along a heat pipe. Then perform experiments to measure the pressure distribution in a simulated heat pipe operating under the same conditions to check the computed results.

Appendix A: Raw Experimental Data

This appendix contains the raw data obtained in the experimental portion of this research. Each file gives the mass flow rate entering the test section and 34 pressure measurements. Figure 2.1 shows the location of the pressure taps in the test section. In general, pressure measurements 1 and 2 were for the pressure above and below the orifice plate respectively, 3 for the pressure at the upstream end of the evaporator manifold, 4 and 5 for the downstream end of the evaporator manifold, 6 and 7 for the atmospheric pressure, 8 - 13 for inside the evaporator section of the porous pipe, and 14 - 34 for inside the condenser end of the porous pipe. Pressure taps 8 - 13 were approximately six inches apart, 13 and 14 eight inches apart, 14 - 34 two inches apart. Pressure tap 34 was located at the end of the condenser section of the porous pipe. The total length of the test section was 6.976 feet. The air supply temperature for all runs was $72^{\circ}\text{F} \pm 5^{\circ}\text{F}$.

Appendix B: Sample Calculations

This appendix includes samples calculations for the pipe calibration and for the first step of the numerical simulation code.

Pipe Calibration Calculations

Figure B.1 Calibration Manifold

Pressure Tap 1 - Pressure upstream of the orifice plate, or
pressure upstream of flowmeter, p_1

Pressure Tap 2 - Pressure downstream of orifice plate, p_2

Q = Mass flow rate

q = Flowmeter mass flow rate reading

A = surface area of the porous pipe

D = porous pipe diameter = 0.625 inches

D_1 = Air Supply Pipe Diameter = 3.062 inches

D_2 = orifice plate bore = 1.0 inch

L = length of porous pipe sample

k = 1.4

C = discharge coefficient = 0.61

β = D_2/D_1 = 0.326584

R = ideal gas constant for air = 53.26 lbf-ft/lbm-°R

X = $(p_1 - p_2)/p_1$

Y = $1 - (0.41 + 0.35 \beta^4)X/k$

Sample Readings from Orifice Plate Measurement of Mass Flow Rate:

p_1 = 114.7224 psia

p_2 = 114.7007 psia

p_3 = 25.19472 psia

p_4 = 25.16627 psia

p_{atm} = 14.3558 psia

T = 538 °R

L = 1.953 inches

X = 0.000189

Y = 0.99994

ρ = $p_1/(RT)$ = 0.5765 lbm/ft³

Q = $D_2 C Y \left[2 (p_1 - p_2)/((1 - \beta^4))^{1/2}/4 \right]$

Q = 0.03604 lbm/sec

A = $\pi D L$ = 0.02663 ft²

ρv = $Q/(A g_c)$ = 0.04206 lbf-sec/ft²

ΔP^2 = $[(p_3 + p_4)/2]^2 - p_{atm}^2$

ΔP^2 = 8,874,344.45 lbf²/ft⁴

Sample Readings from Flowmeter Mass Flow Rate Measurement:

$$p_1 = 15.00665 \text{ psia}$$

$$p_2 = 14.68725 \text{ psia}$$

$$p_4 = 14.68466 \text{ psia}$$

$$p_{\text{atm}} = 14.37227 \text{ psia}$$

$$q = 0.3975 \text{ cfm}$$

$$T = 534 \text{ }^{\circ}\text{R}$$

$$L = 1.875 \text{ inches}$$

$$\rho = p_1/(RT) = 0.07598 \text{ lbm/ft}^3$$

$$Q = q\rho = 0.0005034 \text{ lbm/sec}$$

$$A = \pi D L = 0.025566 \text{ ft}^2$$

$$\rho v = Q/(Aq_m) = 0.000612 \text{ lbf-sec/ft}^2$$

$$\Delta p^2 = [(p_2 + p_4)/2]^2 - p_{\text{atm}}^2 = 189,011.3 \text{ lbf}^2/\text{ft}^4$$

**Sample Calculations for First Increment of Numerical
Simulation Code (x = 0.0 to x = 0.005 ft):**

(The data for these sample calculations is taken from the
raw pressure data file D2209E)

p_u = pressure at the upstream end of the evaporator air
supply manifold

$$p_u = 2791.20 \text{ lbf/ft}^2$$

p_d = pressure at the downstream end of the evaporator air
supply manifold

$$p_d = 2777.88 \text{ lbf/ft}^2$$

p_1 = internal pressure at the upstream end of the evaporator

$$p_1 = 2781.648 \text{ lbf/ft}^2$$

p_1 = pressure at the first pressure tap location in the evaporator

$$p_1 = 2775.931 \text{ lbf/ft}^2$$

p_2 = pressure at the second pressure tap location in the evaporator

$$p_2 = 2767.910 \text{ lbf/ft}^2$$

$$k = 1.4$$

$$D = 0.625 \text{ in} = 0.0521 \text{ ft}$$

$$PL = \text{total pipe length} = 6.976 \text{ ft}$$

$$A = \text{constant from equation 2.1} = 4.679 \times 10^8 \text{ ft}^2/\text{sec}^2$$

$$B = \text{constant from equation 2.1} = 4.2843 \times 10^7 \text{ lbf/ft-sec}$$

$$T = 533.1 \text{ }^\circ\text{R}$$

$$x = 0.005 \text{ ft}$$

$$x_1 = 0.00 \text{ ft}$$

x_1 = axial location of first pressure tap in the evaporator

$$x_2 = 0.50 \text{ ft}$$

x_2 = axial location of second pressure tap in the evaporator

$$x_3 = 0.99 \text{ ft}$$

Assuming the pressure in the evaporator changes linearly from upstream value to its downstream value, calculate the slope of the line.

$$S = (p_2 - p_1)/(PL/2) = -3.8188 \text{ lbf/ft}^2$$

$$\rho_1 = p_1/(RT) = 0.0978 \text{ lbm/ft}^3$$

$$A_m = \pi D^2/4 = 0.002132 \text{ ft}^2$$

$$A_p = \pi D \Delta x = 0.0008184 \text{ ft}^2$$

$$(\Delta p^2)_1 = p_1^2 - p_2^2 = -53,251.844 \text{ lbf}^2/\text{ft}^4 \text{ (negative sign)}$$

indicates mass flow into pipe)

$$K_1 = [(x - x_2)(x - x_3)] / [(x_1 - x_2)(x_1 - x_3)] = 0.985$$

$$K_2 = [(x - x_1)(x - x_3)] / [(x_2 - x_1)(x_2 - x_3)] = 0.0201$$

$$K_3 = [(x - x_1)(x - x_2)] / [(x_3 - x_1)(x_3 - x_2)] = -0.0051$$

$$p(x = 0.005) = K_1 p_1 + K_2 p_2 + K_3 p_3 = 2781.6048 \text{ lbf/ft}^2$$

$$p_m = p(x = 0.005)$$

$$p_{2'} = p_m + 8x = 2791.18 \text{ lbf/ft}^2$$

$$(\Delta p^2)_2 = p_m^2 - p_{2'}^2 = -53,365.587 \text{ lbf}^2/\text{ft}^4$$

$$(\rho v) = -g_m [-B + (B^2 + 4 A |(\Delta p^2)|)^{1/2}] / (2 A) \text{ (from eqn 2.1)}$$

$$(\rho v)_1 = -0.035672 \text{ lbm/ft}^2\text{-sec}$$

$$(\rho v)_2 = -0.035740 \text{ lbm/ft}^2\text{-sec}$$

$$Ma_1 = 0.0$$

u = axial velocity

$$u_1 = 0.0$$

$$a^2 = g_m k p_1 / \rho_1 = 1,281,139.47 \text{ ft}^2/\text{sec}^2$$

$$a = 1,131.87 \text{ ft/sec}$$

$$\dot{m}_1 = 0.0 \text{ lbm/sec}$$

$$(\rho v)_{avg} = [(\rho v)_1 + (\rho v)_2] / 2 = -0.035706 \text{ lbm/ft}^2\text{-sec}$$

$$\rho_2 = p_2 / (RT) = 0.0978 \text{ lbm/ft}^3$$

$$\rho_{avg} = (\rho_1 + \rho_2) / 2 = 0.0978 \text{ lbm/ft}^3$$

$$u_2 = -(\rho v)_{avg} \lambda_p / (\rho_{avg} \lambda_m) = 0.14015 \text{ ft/sec}$$

$$Ma_2 = u_2 / a = 0.0001238$$

$$u_{avg} = (u_1 + u_2) / 2 = 0.07008 \text{ ft/sec}$$

$$Ma_{avg} = (Ma_1 + Ma_2) / 2 = 0.0000619$$

$$\dot{m} = -(\rho v)_{avg} \lambda_p = 0.0000292 \text{ lbm/sec}$$

$$\dot{m}_2 = \dot{m}_1 + \dot{m} = 0.0000292 \text{ lbm/sec}$$

$$\dot{m}_{avg} = (\dot{m}_1 + \dot{m}_2) / 2 = 0.0000146 \text{ lbm/sec}$$

$$\mu = 2.27(10^{-8}) T^{3/2}/(T + 198.6) = 3.82(10^{-7}) \text{ lbf-sec/ft}^2$$

$$M = \text{momentum} = \dot{m} u$$

$$\Delta M = \dot{m}_2 u_2/g_c - \dot{m}_1 u_1/g_c = 1.2720 \times 10^{-7} \text{ lbf}$$

$$\tau_w = [(p_1 - p_2)A_c - \Delta M]/A_c = 0.11238 \text{ lbf/ft}^2$$

$$f = 2 \tau_w g_c / (\rho_{avg} u_{avg}^2) = 15,056.123$$

$$Re_w = 4 \dot{m}_{avg} / (\pi D \mu g_c) = 29.031$$

$$Re_w = (v)_{avg} D / (\mu g_c) = -151.360$$

Appendix C: Numerical Simulation Code and
Sample Results

The following pages are a listing of the computer code used for the numerical simulations. The code is written in FORTRAN 77 and some sample results are also included following the program listing.

```

*****
*
*       ONE-DIMENSIONAL HEAT PIPE SIMULATION PROGRAM
*
*****

```

This program uses one-dimensional incompressible and compressible flow models to solve for the flow properties and friction coefficients in a closed porous pipe with blowing and suction. An incompressible model consisting of Newton's second law and incompressible flow equations is used to calculate flow properties until the Mach number reaches 0.01. After that, the compressible model, consisting of the continuity equation and Shapiro's method of influence coefficients, is used to solve for the properties.

DEFINITION OF VARIABLES:

A	Constant used in wall boundary condition (ft^2/sec^2)
AC	Cross-sectional area of the pipe (ft^2)
AP	Surface area of DX increment (ft^2)
B	Constant used in wall boundary condition ($\text{lb}/\text{ft}/\text{sec}$)
C2	Speed of sound squared (ft^2/sec^2)
D	Pipe inside diameter (ft)
DMOM	Change in momentum across DX increment (lbf)
DX	Spacial step size (ft)
DW	Change in mass flow rate due to mass transfer at the wall ($\text{lb}/\text{m}/\text{sec}$)
F	Friction factor
FS	Shear force over the increment DX (lbf)
FSSUM	Summation of all the incremental shear force values over the entire pipe (lbf)
FUD	Constant to account for the statistical variation of the porous pipe properties
GAM	Ratio of specific heats
GC	Constant in Newton's second law ($\text{lb}/\text{m}/\text{ft}/\text{lbf}/\text{sec}^2$)
M1	Mach number at upstream end of DX increment
M2	Mach number at downstream end of DX increment
M12	M1 squared
M22	M2 squared
MSBAR	Average of M12 and M22
PATH	Atmospheric pressure (entered in psia then converted lb/ft^2)
PCOND	Condenser environment pressure (lb/ft^2)
PEVAPD	Downstream evaporator environment pressure (entered in psia then converted to lb/ft^2)
PEVAPU	Upstream evaporator environment pressure (entered in psia then converted to lb/ft^2)
PEX	Environment pressure (lb/ft^2)
PL	Pipe length (ft)
P0	Upstream end of porous pipe pressure (lb/ft^2)
P1	Static pressure at upstream end of DX increment (lb/ft^2)

P2 Static pressure at downstream end of DX increment
 (lbf/ft²)
 R Ideal gas constant for air (lbf-ft/lbm/°R)
 REW Radial Reynolds number
 REX Axial Reynolds number
 RHO Density (lbm/ft³)
 RHOV1 Mass flux through the wall at the upstream end of the
 DX increment (lbm/ft²/sec)
 RHOV2 Mass flux through the wall at the downstream end of the
 DX increment (lbm/ft²/sec)
 RMU Viscosity (lbf-sec/ft²)
 S Slope of the evaporator environment pressure line
 (lbf/ft²/ft)
 TW Wall shear stress (lbf/ft²)
 T0 Total air temperature (°R)
 W1 Mass flow rate at the upstream end of the DX increment
 (lbm/sec)
 W2 Mass flow rate at the downstream end of the DX incre-
 ment (lbm/sec)
 XL Local axial position (ft)
 XND Nondimensional axial location (XL/PL)
 X(1)-X(30) Axial location of pressure measurements (ft)

VITA

Second Lieutenant Constance A. Holladay was born on 23 March 1964 in Memphis, Tennessee. She attended Overton High School in Memphis, Tennessee and graduated in 1982. From September 1982 to May 1986, she attended Memphis State University where she studied Mechanical Engineering. Upon graduation, she received the degree of Bachelor of Science in Mechanical Engineering and a commission in the USAF through the ROTC program. Following graduation, she entered the School of Engineering, Air Force Institute of Technology, in May 1986.

19. Research was performed to verify previously obtained friction coefficients for compressible, laminar and turbulent flow in a simulated heat pipe for intermediate mass injection and suction rates. The research was divided into two main parts: an experimental study and a numerical study. In the experimental study, the axial pressure distribution along the simulated heat pipe, consisting of a long porous tube with air as the working fluid, was measured for various mass flow rates. The experimentally measured axial pressure distributions were then used as input to a one-dimensional numerical simulation to determine the friction coefficients. Finally, the results were compared to the previous research.
